This paper was prepared for presentation during the 19<sup>th</sup> International Congress of the Brazilian Geophysical Society held in Rio de Janeiro, Brazil, 18-20 November 2025. Contents of this paper were reviewed by the Technical Committee of the 19<sup>th</sup> International Congress of the Brazilian Geophysical Society and do not necessarily represent any position of the SBGf, its officers or members. Electronic reproduction or storage of any part of this paper for commercial purposes without the written consent of the Brazilian Geophysical Society is prohibited.

This study investigates the complex tectonic architecture of southeastern Brazil in the context of crustal block assembly and amalgamation during the construction of the Gondwana supercontinent. Conducted within the framework of the Petronas Petróleo Brasil Multiphysics Project, the research integrates long-period magnetotelluric (MT) data with multiple geophysical datasets to characterize deep lithospheric structures and tectonic processes associated with Gondwana evolution. MT data were acquired at 100 stations distributed over an area of approximately  $500 \times 400 \text{ km}^2$ , arranged along five NW–SE-oriented profiles with spacing between 15 and 25 km. The three-dimensional electrical resistivity model was generated using the ModEM-ON inversion package, incorporating full impedance tensors and Tipper functions derived from the MT data. The multidisciplinary integration of this model with gravity, seismic tomography, geothermal, and magnetic data enabled the identification of key lithospheric structures and the development of a coherent tectonic evolution model for the region. Under the São Francisco Craton, a prominent conductive anomaly spatially correlated with high seismic velocities and low geothermal flux, along with a well-defined lithosphere–asthenosphere boundary, suggests post-collisional crustal rejuvenation processes. In the Ribeira Orogen, well-defined suture zones were identified in both the geoelectrical model and the seismic tomography, documenting subduction and collision events that occurred during the Neoproterozoic. The most remarkable feature in the central portion of the orogen is an extensive resistive body, spatially coincident with high seismic velocities and reduced heat flow, interpreted as unequivocal evidence for the presence of a microcontinent (the Paraíba do Sul Microcontinent) incorporated during the amalgamation of Gondwana. Additionally, anomalous conductive zones at the boundary between the Ribeira Orogen and the Cabo Frio Terrane, associated with outcrops of oceanic magmatic arc rocks, support a Cambrian accretionary scenario. These results provide robust evidence that refutes previous models suggesting an intracontinental evolution for southeastern Brazil, instead highlighting the fundamental role of Neoproterozoic–Cambrian accretionary processes, including magmatic arc formation, ocean closure, and continental block collisions.
